ABSTRACT

Dynamic hip screw (DHS) fixation is considered standard treatment for most intertrochanteric fractures. However, excessive sliding at the fracture site and medialisation of femoral shaft may lead in fixation failure. In contrast, fixed-angled 95° condylar blade plate (CBP) has no effective dynamic capacity and causes little bone loss compared to DHS. We compared the outcome of 57 consecutive unstable intertrochanteric fragility fractures treated with these two fixation methods. CBP instrumentation is more difficult requiring longer incision, operating time and higher surgeon-reported operative difficulty. The six month post-operative mortality rate is 16%. Post-operative Harris hip scores were comparable between the two methods. Limb length shortening more than 20 mm was 6-fold more common with DHS. In elderly patients with unstable intertrochanteric fragility fractures, fixed angled condylar blade plate appears to be a better choice than dynamic hip screws for preventing fixation failures.

Key Words:

Unstable Intertrochanteric Fractures; Extramedullary fixation; Low Fragility; Dynamic Hip Screw; 95° Condylar Blade Plate

INTRODUCTION

Fragility fractures can be caused by a fall from a standing height or less. Osteoporosis which leads to bone fragility is considered the major contributing factor to fragility fractures and is directly linked to risk of hip fracture. Every year there are 250,000 hip fractures in the United States, and it is predicted that this number will double in the next 40 years¹. A similar increase is expected in Asia². In general, as the population ages, the incidence and cost for treating these

injuries is going to increase dramatically^{3,4}. Hip fractures are associated with high morbidity and mortality, a rate of up to 20% can be expected in the year following the injury⁵. The majority of those who survive are disabled with only 25% able to resume normal activities⁶.

About half of the hip fragility fractures are intertrochanteric fractures. Dynamic hip screw (DHS) fixation has been considered the gold standard for treatment of stable intertrochanteric fractures^{7,8}. DHS allows controlled collapse of the fracture followed by progressive stabilization. However, there are divergent opinions about the fixation of unstable intertrochanteric fractures in the elderly. Authors reported high failure rates (range: 3% to 26%) for DHS fixation in unstable intertrochanteric fractures. Failure usually occurs due to loss of fixation of the lag screw with resultant varus angulations and medial collapse at the fracture site; plate pull-off from the shaft; implant disassembly; or fatigue failure in cases of delayed union^{9,10,11,12}. Orthopaedists have questioned whether the fixation should be dynamic by default allowing fracture compression and union at the cost of reduced femoral neck length and medialisation of the femur shaft. Or should rigid fixation applied to restore the pre-fracture anatomy to achieve immediate stability for early mobilization in a race towards fracture union before implant fatigue?

There are limitations as to how much of dynamic fracture compression is desirable. DHS fixation permits fracture compression along the femoral neck that leads to femoral neck shortening; there is also an inherent tendency towards medialisation of the femoral shaft¹³. Jacobs et al found that the average length of lag screw sliding was 5.3 mm in stable fractures, and 15.7 mm in unstable fractures. Excessive sliding (more than 15 mm) correlates to higher prevalence of fixation failure⁴, and is also associated with increased post-

operative pain and decreased post-operative mobility¹⁴. Parker found that if medialisation of more than one-third of the femoral shaft diameter occurs at the fracture site, there is a seven-fold increased risk of fixation failure¹⁵.

A fixed-angled 95° condylar blade plate (CBP) can be used in these difficult unstable fractures as well as in revision fixation for failed intertrochanteric fractures¹⁶. This technique results in improved resistance to rotation of the proximal fragment, as it has no effective dynamic capacity. This is due to the fact that, on loading, the hip joint reaction force is 159° towards the vertical plane. CBP does not allow the proximal fragment to slide laterally thus avoiding the undesirable medialisation of the shaft.

We compared these two extramedullary fixation devices in the treatment of unstable intertrochanteric fractures.

MATERIALS AND METHODS

Consecutive patients admitted in 2004 with unstable intertrochanteric fractures were prospectively randomized (by drawing lots from sealed envelopes) into two study groups. The study was approved by the hospital ethics committee. Consent was also obtained from patients or, in cases where they were confused, from their caretakers. Inclusion criteria were: 55 years of age or older with low traumatic intertrochanteric fracture classified as AO/OTA Type 31 A2.2 and A2.3 and Kyle Type III and Type IV. They were fractures with comminution, loss of postero-medial calcar, subtrochanteric extension, and reverse oblique fracture pattern¹⁷. Two-part fractures were excluded since they are considered stable fractures. Patients with fractures associated with polytrauma, pathological fractures, and previous surgery on the ipsilateral hip or femur were excluded.

There were 61 patients with 63 hip fractures treated during the study period. 57 hips are included in the results: 31 treated with DHS (Dynamic Hip Screw, Synthes-Stratec, Oberdorf, Switzerland) and 26 treated with CBP (95° condylar blade plate; Synthes-Stratec, Oberdorf, Switzerland). Six patients were excluded as five were unfit for surgery and therefore treated conservatively, while one was transferred to other centre. Surgery was performed within four days in all patients. Best possible alignment is achieved either by closed manipulation under fluoroscopy control or open reduction. Standard method of instrumentation and fixation were performed under fluoroscopy control. The modified Harris Hip Score without assessing the hip motion was used to determine pre-fracture status, and the Harris Hip Score (HSS) was used for post-operative 3rd and 6th month functional assessment. Plain radiographs were taken before and one day post-operatively, followed by repeated radiographs at 1st, 3rd and 6th month postoperatively. Post-operative rehabilitation was

standardized in both groups with emphasis on early gain of protected partial weight-bearing using a walking frame before discharge.

Categorical variables were analyzed using chi-square tests of association (ambulatory status). Continuous variables were assessed by One-way ANOVA test or Student's t-test (Harris Hip Score, operating time, blood loss and Visual Analogue Score of operating difficulty). The level of significance was set at $p < 0.05$.

RESULTS

The subjects in both groups were similar in terms of demographic and premorbid functional status (Table I). With CBP the incision was typically longer and blood loss was also more but these differences were not statistically significant. Skin to skin operative time was significantly longer using CBP, though the clinical relevance of a mean of extra 20 minutes is unclear. When coupled with a significantly higher surgeon-reported Visual Analogue Score (VAS) in operating difficulty, a longer operative time rightly reflects the difficult CBP instrumentation (Table II).

Within 3 months following surgery, 10% of the patients passed away from medical complications unrelated to their surgery, with another 5% in the following 3 months, contributing to a 16% mortality 6 month after surgery (Table III). Harris Hip Scores 3 months and 6 months after surgery were comparable between the 2 groups. Twenty-one per cent of surviving patients did not regain the ability to walk when assessed 6 months after surgery. There was no correlation between the ability to walk and limb length shortening or choice of implant. Despite early surgical intervention, the 16% 6 month mortality rate and the high rate of failure to return to ambulatory status were attributed to the systemic nature of osteoporosis in the elderly.

Complications

There was no recognised deep vein thrombosis, pulmonary embolism, or deep infection. There were 3 fixation failures in each group due to suboptimal surgical fixation (Table IV). In the DHS group, poor reduction with medialisation of femoral shaft by 25%, a short lag screw and/or maximal initial sliding leaving no room for further fracture impaction, eventually led to superior cut out in 3 patients (Figure 1). This resulted in two patients remaining bedridden, and in the third patient with no acetabulum involvement, revision fixation was performed 6 months later. Shortening (leg length difference of more than 20 mm, clinically reported and radiologically measured) was significantly more common in the DHS group.

In the CBP group, the failure to primarily restore neck-shaft angle, as evidenced by the post-operative pelvic antero-posterior film, led to one case of excessive varus, nonunion

and subsequent implant fatigue at the 4th postoperative month. There was one nonunion leading to superior cut out in the CBP group (Figure 2). The overall failure rate, when limb length shortening and fixation failures were considered,

was lower in group CBP and approaching statistical significance with p value at 0.51. Medialisation of femoral shaft was not compared, as it was not possible with the fixed-angle CBP.

Table I: Demographic and premorbid functional evaluation and fracture pattern

	Method of fixation	
	DHS (n=31)	CBP (n=26)
Women: Men	28:3	17:9
Age (years) : mean (range)	78 (55-100)	78 (58-96)
QCT scan (mg/cm3) : mean BMD	74.72	77.66
Modified pre fracture Harris HIP score; mean (range)	80 (52-91)	77 (52-91)
Walking ability, prefracture		
No aids	21	17
Aids	10	9
Non walker	0	0
Fracture Type (AO/OTA type 31)		
A2.2	20	18
A2.3	11	8

Table II: Per operative parameters

	DHS (n=9)	CBD (n=10)	P value
Operating time (min) : mean (range)	74 (50-120)	94 (45-135)	0.001 ^b
Operating blood loss (litre) : mean (range)	0.19 (0.05-0.80)	0.24 (0.05-0.80)	0.27 ^b
Operating difficulty ^a mean (range)	3.4 (2-8)	4.3 (2-8)	0.018 ^b

DISCUSSION

For the fixation of stable intertrochanteric fractures, there exists a plethora of choices of implants, whereas the ideal implant remains elusive for unstable intertrochanteric fractures. Unstable intertrochanteric fractures especially those with a posterior medial defect are more prone to complications. Loss of posterior medial support leads to increase hip screw telescoping and limb shortening. Further, these defects also lead to increased load transfer to the tip of the dynamic hip screw, thereby increasing superior cut out. Loss of fixation of the lag screw in an osteoporotic head, with resultant varus angulation and medial collapse at the fracture site can also occur¹⁸. Independent of the type of implant used, patients with unstable trochanteric hip fractures and osteoporotic bone are at the highest risk for implant failure¹⁹.

Kaufer determined that the strength of the implant-fracture composite is based on 5 variables: bone quality, fracture geometry, fracture reduction, placement of implant, and implant used²⁰. A CT scan of an intertrochanteric fracture may reveal poor density of trabeculation and even emptiness within the head. Maximum bone density is likely found at the site where the compressive and tensile trabeculae coalesce, in the centre-centre region of the femoral head²¹. An ideal implant should engage this region while taking as little remaining strong bone as feasible. The CBP at 95° to the femur shaft is wedged below the densest trabeculae in the centre-centre region of the femoral head. There is little bone loss in preparing the sitting bed for CBP especially as compared to DHS that requires bone coring.

Of concern is unstable fracture geometry that include fractures with increased comminution, loss of postero-medial calcar, subtrochanteric extension, and reverse oblique fractures. Anatomic reduction of femoral neck length, axial length, and neck-shaft angle must be achieved before implantation. In addition to the degree of osteoporosis, the rate of superior cut out is strongly correlated to surgical technique. Baumgaertner *et al* demonstrated that enhanced surgeon awareness of short tip-apex distance (TAD) decreases the risk of fixation failure²².

Choice of implant should not be routine but customised according to fracture characteristics. Unstable fractures with osteoporosis are reported to have failure rate of more than

50%²³. In such cases DHS may still yield good outcome (Figure 3) but DHS should not be automatically the first choice for treatment. Our results indicate that unstable intertrochanteric fractures, treated with fixed-angled 95° CBP have similar outcomes and near statistically significant lower failure rate compared to DHS. This fixed-angle device acts as a bridge plate across the fracture site, and therefore may be of value in severe osteoporotic bones as well as in comminution where dynamic fixation may lead to excessive interfragmentary compression. Conversely, the two failure patterns of CBP observed in present study, namely implant breakage and nonunion, may be due to lack of interfragmentary compression. For optimal application of the bridging plate principle across fracture comminution, the authors recommend the use of a longer 7 or 9-hole side plate CBP with 4 distal screws and 1 proximal lag screw for the femoral head. Subsequent cases conducted using this technique consistently led to fracture union (Figure 4).

The present study has several limitations. Though both devices analyzed in this study are extramedullary using similar surgical exposure, the more difficult CBP instrumentation may be subject to performance bias; hence a larger studied population is warranted. Secondly, only some of the patients underwent a Quantitative Computed Tomography (QCT) scan. Among the patients who were scanned, there was no difference in bone mineral density detected between the two groups, but inclusion of all patients may have revealed subtle differences (Table V). Thirdly, although body mass index was not studied, it may be an important factor in early stability of fracture-implant construct and subsequent union rate. Of course, follow-up longer than 6 months would have been optimal. Lastly as the focus was on extramedullary fixation, the present study did not include any intramedullary device options for these fractures.

CONCLUSION

In the treatment of fragility fractures, it is important to recognise unstable fracture geometry and customise the choice of implant according to the fracture characteristics. In elderly patients with unstable fragility intertrochanteric fractures, fixed angled condylar blade plate appears to be a better choice than dynamic hip screws with a lower rate of fixation failure.
